Abstract

Class imbalance is very common in data analysis, it occurs when the proportion of classes among the data are different. With the success of deep learning in many domains such as computer vision, natural language processing, and more recently with time series, the requirement of a large amount of balance data is mandatory. The imbalance leads classifiers to overestimate the majority classes due to their proportion. Thus, data belonging to minority classes may be misclassified. Imbalanced data is common to many real-world problems, such as in the medical field with the prediction of rare but important diseases or the detection of anomalies in the manufacturing field. There are many solutions to overcome this problem. In particular, oversampling, which consists in generating new data to balance the minority classes. Several strategies exist to oversample data such as duplicating existing data (or random oversampling), using data augmentation techniques or other approaches such as SMOTE which is very popular. Although advanced data augmentation techniques such as generative models are increasingly studied, basic data augmentation techniques remain widely used because of their ease of use and speed. We empirically evaluate the impact of balancing time series data sets using data augmentation on classification performances considering standard and neural networks classification models. Our results suggest that certain data augmentation techniques are more effective when applied to data with specific characteristics and within particular domains.

1. Introduction

data analysis. Supervised learning is most often used as a method to determine whether a data belongs to a particular class. The main idea of this approach is to produce a function based on the training data, with a view to predict to which class the studied data belongs. This means that the success of using of a learning classification algorithm depends largely on the selection of the data in the training database.

With the success of deep learning in many domains such as computer vision, natural language processing and more recently with time series, the requirement of a large amount of balance data is mandatory. Indeed issues like data scarcity and data imbalance can lead these

Classification tasks are among the most popular in

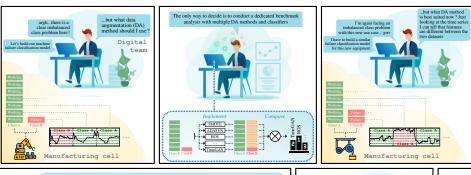

A popular solution to remedy the lack of data is data augmentation. It aims at creating synthetic data from the input space. However, most studies use data augmentation to increase the samples of the train set with the same distribution [1]. It has been shown that increasing the amount of data in time series datasets can drastically improve the accuracy of a deep learning model

Preprint submitted to Elsevier

models to overfit and thus affect the classification performances. Class imbalance in the training data leads classifiers to over-estimate the class associated with the majority group due to its increased proportion. As a result, data belonging to the minority group might be misclassified. However, it is often impossible to create large balanced data sets from real data. This problem is related to many real-life applications such as medical diagnosis with electrocardiogram (ECG) data analysis; fraud detection in banking operations, network intrusion detection networks, risk management, the prediction of technical equipment failures in manufacturing field with sensor data.

while having a slight negative impact on some datasets in the worst case.[] Although minority classes can benefit from more samples, majority class samples also increase, and thus problems related to imbalanced data persist. Balancing class distribution becomes crucial when dealing with imbalanced datasets in classification tasks. Imbalanced data can impede model performance by causing overfitting to the majority class, resulting in misclassification of minority class instances. In highstakes scenarios, such as detecting medical anomalies or fraud, achieving a balance in class representation through techniques like data augmentation or resampling becomes imperative. This empowers the model to allocate sufficient attention to critical yet rare cases, ultimately enhancing the performance and reliability of classification outcomes.

In the literature, studies on balancing techniques focus mainly on benchmarking these techniques through global evaluations across various datasets. However, there is a noticeable gap in intensive investigations that dive into the specific conditions under which certain techniques perform better based on the inherent characteristics of individual input datasets. Such in-depth analyzes could shed light on the optimal strategies for addressing class imbalance in diverse scenarios, guiding practitioners to choose the most suitable approach depending on factors like dataset size, class imbalance, and dataset variance.

In this study, we empirically explore the effects of balancing time series datasets on classifier performance. This investigation covers a diverse set of classifiers, ranging from traditional machine learning algorithms to deep neural networks. To address class imbalance, we employ both fundamental and advanced data augmentation techniques sourced from existing literature. Additionally, we delve into the intrinsic characteristics of the time series datasets. Taking into account factors such as the number of data, data variance, or class imbalance levels, we discern the optimal data augmentation method for specific dataset profiles. Finally, our study culminates in the creation of a decision support tool. This tool uses both the characteristics of the dataset and the empirical findings to provide tailored recommendations for selecting appropriate data augmentation techniques. It also provides an estimate of the potential improvement of classifier performance through the inclusion of synthetic data.

This paper is organized as follows: Section 2 presents a comprehensive review of the existing literature concerning oversampling with data augmentation techniques to address data imbalance in time series datasets. In Section 3, we examine the current practices and approaches used to balance time series data, with a particular focus on how most studies compare various data augmentation techniques. Finally, Section 4 outlines our proposed methodology to conduct a comprehensive

analysis of the suitability of data augmentation techniques in the context of time series data. In addition, we provide a description of a decision support tool designed to assist practitioners in selecting the most appropriate data augmentation technique for their input data based on the intrinsic characteristics of the time series.

2.1. Imbalance data handling

2.1.1. Strategies

Two main approaches can be distinguished to address imbalanced data. The first corresponds to cost-sensitive or algorithm-level strategies [The foundations of cost-sensitive learning]. It aims to adjust the training procedure of classic classification algorithms to accommodate data imbalance and lessen the detrimental impact on minority classes classification performance. Every misclassification error does not have the same cost depending on the occurrence of each class. Data with fewer occurrences have a much greater weight in the training.

The second relies on data-level methods. It aims to artificially modify the training set to reduce data imbalance. One can find three methods to do so: undersampling, oversampling, and hybridsampling. Undersampling [] involves removing a certain amount Removing 168 of samples from the dominant classes. data may potentially lead to a loss of information, 169 particularly when the original training dataset is not sufficiently large, and thus may reduce the effectiveness of classification. However, undersampling remains a fast and efficient approach to balance the dataset, as it only utilizes a subset of the majority class for training. Oversampling involves increasing the number of samples in the minority classes. But the manner in which this is achieved raises questions. On the one hand, the synthesized data should closely resemble the original data, and on the other hand, overly similar samples may lead to overfitting issues. Finally, hybridsampling combines both oversampling and undersampling approaches. In this paper, our focus is specifically on oversampling methods for time-series classification.

2.1.2. Oversampling

One naive approach to oversampling, referred to as 187 "Random Oversampling"[?], involves randomly selecting samples from the minority class and duplicating 189 them. At first, the field of computer vision provides 190 numerous more sophisticated oversampling methods 191

[]. They employ data transformation i.e. modifying existing data such as geometric transformations (e.g. flipping, rotating, jittering, cropping) and photometric transformations (e.g variations in colorimetry, contrast, exposure, white balance). Instead of transforming existing data, a widely used method called Synthetic Minority Oversampling Technique (SMOTE) [] involves combining existing data to create new samples. SMOTE generates new instances by interpolating existing neighbor samples selected through K-Nearest Neighbors. This technique has inspired several variants, including Borderline-SMOTE[], SVM-SMOTE[], ADASYN[], and others.

The lack of a standard procedure for data augmentation in time-series recognition is a major limitation. While data augmentation is a widely used technique in image recognition, X pointed out that the absence of a standard procedure for data augmentation in time-series recognition is a major obstacle. "while data augmentation is a common practice in image recognition with neural networks, it is not established as a standard procedure for time series recognition.". In fact, more advanced tools such as [2] provide an impactful insight on which data augmentation techniques is the best considering the input data. It uses reinforcement learning to learn the best augmentations policy from the data, treating the generalization of the target model as a reward signal. More recently, NVIDIA developed the NVIDIA Data Loading Library (DALI) facilitates image augmentation during deep learning training by offering automatic augmentation policies, such as AutoAugment, which enable probabilistic, policy-driven, random selection, and application of image transformations, and can be easily integrated and customized within the data processing pipeline through a straightforward API, enhancing computational efficiency and flexibility in training workflows.

Although many techniques in computer vision can be adapted for time-series classification, there is a need for specific techniques tailored to time-series data. Iwana et al.[1] provide a comprehensive taxonomy of such techniques in their survey, including Jittering, Scaling, and introducing more specialized techniques for time series, such as Time Warping. The requirement of minority classes oversampling in imbalanced time-series classification (ITSC) has spurred the development of adaptable data augmentation techniques, originally employed in computer vision, to be applied to time series such as TSMOTE [] and DTW-SMOTE [].

More recently, advanced techniques that exhibit remarkable performance in image processing have been intro-

185

147

148

duced, albeit at a higher computational cost: generative 243 models. Variational Auto-Encoders (VAEs) [] aim to 244 directly estimate the probability distribution of the data, 245 while Generative Adversarial Networks (GANs) [] indi- 246 rectly approximate the probability distribution by train- 247 ing two neural networks to compete against each other, 248 one generating synthetic data and the other discriminating between synthetic and real data. Additionally, 250 a class of score-based diffusion models, pioneered by Song and Ermon [], has emerged, outperforming GANs. 252 In the context of time series, new architectures and vari- 253 ations of generative models, such as TS-GANs [] for 254 GANs and Schrodinger bridge [] for diffusion models, 255 have been proposed. Notably, generative models differ from the techniques mentioned earlier, as they aim to estimate the data probability distribution in order to generate new data that conforms to this distribution, rather 258 than modifying existing data.

Although advanced data augmentation techniques are increasingly studied [Time-series Generative Adversarial Networks] [GENERATIVE ADVERSARIAL NET-WORKS IN TIME SERIES: A SURVEY AND TAX-ONOMY], basic data augmentation techniques remain largely used due to their ease of use as well as their poor resource blow. The application of these techniques, which are primarily used to address the issues of data scarcity and incompleteness in deep learning model training, can also serve as a potential remedy for class imbalance by oversampling the underrepresented classes.

2.2. Time Series Classification (TSC) features

Utilizing features that characterize time series 273 datasets offers valuable advantages in enhancing anal- 274 ysis tasks such as classification. Indeed, extracting relevant features can help to gain deeper insights. More- 276 over, given the abundance of data augmentation techniques available in the literature for time series data 278 augmentation, it sounds interesting to know which techniques is more suitable to what kind of input data based 280 on their caracteristics. In fact, [1] already conducted 281 comparative comparative assessments of data augmen- 282 tation methods using different neural network classi- 283 fiers. Its results turned out to show that the choice of 284 classifier is important depending on the input data. In 285 other words, the impact of a data augmentation method may vary depending on the choice of classifier. To do 287 so, it extracted 6 properties as well as the application 288 domain of the input dataset. However, this previous 289 research only considered neural network-based classifiers, a limited set of data augmentation methods and analyze big scale characteristics of time series dataset.

We believe that using additional features that capture more finer properties of the input time series data help us to get more insight.

To this end *hctsa* (highly comparative time series analysis) toolbox [3] propose an architecture to extract over 7,700 time series features. However the relevance of all features as well as the computational cost of such features make it difficult to use with real-world data. In order to reduce redundancy of informations and the computation time, [3] introduce *catch22* (CAnonical Time-series CHaracteristics), a pipeline to reduce all the set of features to a subset of 22 the most useful and complementary characteristics for classification.

2.3. Benchmarking studies of oversampling methods & Paper positioning

Time series data introduces unique challenges due to its high dimensionality and temporal nature. They exhibit strong correlations between neighboring attributes, making the generation of consistent synthetic data particularly complex. This complexity partly accounts for the limited availability of data generation techniques for time series compared to image data. Sophisitized methods have been studied to augment time-series for oversampling purpose while preserving the internal structure of the data.

2.3.1. Time Series augmentation for oversampling

Several sophisticated methods have been suggested to oversampling minority classes while preserving the internal structure of the data. One such approach is the Mahalanobis distance-based sampling technique, which generates synthetic data that align with the covariance structure of the minority class, as proposed in [4]. However, it is not effective for datasets with a large number of dimensions, such as time series. Recently, [5] proposed a new temporal oriented smote variant T-SMOTE. It aims to generate more samples near the class border for minority classes by synthesizing samples along the line segment between a given minority data and its temporal neighbor. This paper realizes a comparison between T-SMOTE and 8 state-ofthe-art oversampling techniques (SMOTE, Bordeline-SMOTE, ADASYN, MWSMOTE, MBS[6], INOS and MBO [7]). Overall, T-SMOTE outperforms all other techniques on 10 well-known datasets from the literature using a LSTM-based model.

However, many of these studies tend to focus on a broad comparison of new techniques with existing methods, emphasizing overall performance metrics. They often lack a detailed analysis specifying the particular scenarios or conditions in which a newly proposed

Table 1: Models and Data Augmentation Techniques

Model	Description
Multilayer Perceptrons (MLPs)	Basic neural network architectures consisting of multiple layers of interconnected nodes.
Random Forest (RF)	Ensemble model that combines multiple decision trees.
TimeSeries Random Forest (TS-RF)	Variation of Random Forest designed for time series data.

2.3.2. Comparison between oversampling method with salar sal

Among tabular data oversampling techniques, stud- 330 ies have investigated the impact of different oversampling techniques on classifier performance with tabular data. It has been shown that, in general, oversampling seems to be a feasible solution to slightly improve the 334 performance of classifiers [8]. It allows in particular 335 to reduce the classification errors on the minority class. 336 In addition, these studies suggest that some techniques are overall better than others. [9] performed an empir- 337 ical analysis of 85 SMOTE variants over 104 datasets. They categorize oversampling techniques based on their main operating principle (e.g. noise removal, dimension reduction, or density-based) and characterize the 341 datasets by three main attributes: The Imbalance Ratio, 342 the number of samples in the minority class, and the to- 343 tal number of samples. Their conclusion emphasized 344 that oversampling is a reliable solution to improve im- 345 balance classification performance, that more advanced techniques do not necessarily perform better than basic smote, and that some techniques globally perform better than others. But even if this categorization permits 349 the identification of which techniques perform the best 350 in which scenario, it only considers class distribution attributes without considering data-based attributes. [10]

performs the same type of experimentation on 96 synthetically generated imbalanced binary datasets. Each generated dataset has its own characteristics: size, clusters by class, number of features, and imbalance ratio. 4 oversampling techniques are studied using 5 different classifiers. This study shows that although performance is generally better with oversampling, the intrinsic characteristics of each dataset significantly impact the performance obtained.

The reviewed studies employ data generation techniques to oversample datasets in order to achieve a balanced distribution of classes. However, these studies tend to focus on a limited range of "basic" oversampling techniques, as well as a short list of classifier.

2.3.3. Paper positionning

The intrinsic relationship between data features and the appropriateness of various data augmentation techniques, particularly in oversampling, is not extensively explored in the existing literature. Findings from studies that focus on tabular data often imply that no single oversampling technique universally excels across all datasets [9]. The effectiveness of a technique can depend on the unique characteristics inherent in a dataset, influencing its capacity to enhance classification performance. When it comes to time-series data, the complexity further complicates the applicability of augmentation techniques, limiting the usability of certain methods. Hence, there is a pressing necessity to deepen our understanding of the conditions under which various augmentation techniques, ranging from basic to sophisti-

cated, can be most effectively employed for oversam- 402 pling within diverse datasets. 403

Consequently, there is a need to analyze and determine which oversampling techniques are more suitable for specific datasets, based on their intrinsic characteristics. In this paper, we address this gap by presenting a comprehensive study investigating the impact of oversampling on classification performance, taking into account the characteristics of the dataset, including more advanced features such as cath22. Through this study, we aim to use a machine learning model that can predict the expected output performance from a classifier based on the input dataset features. This model acts like a decision support system, assisting AI practitioners in effectively oversampling their time-series datasets using data augmentation techniques, particularly when faced with class imbalance.

3. Data balancing: current way of practice

In a real-life context where a developer is faced with imbalanced data, it comes down to the basic scenario of completely balancing the dataset with popular data augmentation techniques. This scenario is consistent with the studies presented above. Each technique is compared for its overall performance. The user simply chooses the one he thinks is most effective, without worrying about whether it really fits his input data.

First, we adopt this systematic approach to assess the performance of 6 time series classification with 6 data augmentation techniques across multiple datasets. This allows us to rank the techniques based on their overall performance.

The table in 1 presents the 6 selected models for time series classification, alongside the 6 popular data augmentation techniques specifically designed for time series data. Detailed descriptions of each model and the corresponding data augmentation parameters can be found in Appendix .1.2.

To carry out the experiment, we first split the imbalanced dataset into a training set and a testing set. Initially, we train the classifier on raw data without any
augmentation and evaluate its performance on the test
set. Next, we completely balance the training set using
a data augmentation method. We then train the classifier
model on the new balanced/augmented dataset and assess its performance on the same testing set. To ensure
reliable results, we repeat this process 20 times and take
the mean performances.

448

Based on our initial experiment, we have successfully evaluated the performance of various techniques when

paired with different classifiers. In particular, we have observed that the effectiveness of a specific data augmentation method can vary depending on the classifier employed.

The graph depicted in 3 illustrates that employing jittering to address data imbalances tends to yield positive results when used in conjunction with neural networks. However, its impact appears to be less pronounced when applied to kernel classifiers.

Furthermore, we observed that when using a specific classifier, one method can produce mixed results. In 2, we use green to represent a positive improvement in the classification performance with augmentation and red to indicate a negative impact for the KERNEL classifier. We notice that D_4 datasets and its modified version see that while its performance to be degraded when oversample with jittering and time warping techniques, using SMOTE tends to improve the performances. Identically, dataset D_{22} and its modified version benefit from oversampling with all techniques except with jiterring.

Based on our preliminary results, it is challenging to conclude on the effectiveness of data augmentation techniques to achieve balance in our datasets. Our findings suggest that the outcomes tend to be highly dependent on the specific choice of classifier, but also of the dataset. This variability underscores the importance of considering these factors when using data augmentation. Further investigation and analysis are required to fully understand the intricate relations between data augmentation, classifiers, and datasets in the context of achieving effective data balance.

4. Data balancing decision support for TSC

4.1. Data Acquisition, Balancing Classification

In this experimental study, we are dealing with an imbalanced dataset and employing a classifier model. The main objective is to assess the impact of different data augmentation methods on the performance of the classifier. We aim to compare the classifier's performance when using data augmentation versus when not using it and thus get the performance improvement when using data augmentation. In order to extract relevant informations, we need to gather a significant number of experiments with various type of data.

We generate new datasets based on a modification of one of the characteristics of the initial datasets from the UCR time series: imbalance. We have chosen to focus essentially on a variation of this feature, as it corresponds to the entry point from which a user will want to balance his datasets. However, it could be interesting to

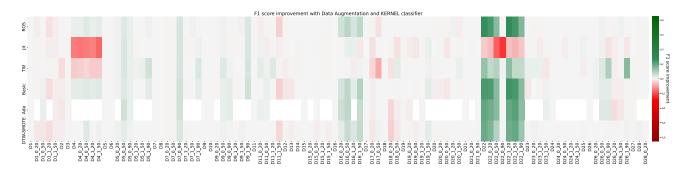

Figure 2: F1 score improvement after balancing for the KERNEL classifier Green indicates improvement in performance; red indicates degradation in performance. White indicate that the oversampling method cannot be applied in the scenario

483

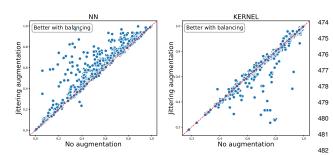

Figure 3: Neural Network and Kernel Classification performances with Jittering augmentation for balancing

play with other features. To do so, we artificially create a minority class by randomly removing $k \in \{20, 50, 90\}$ % of data belonging to a class. To guarantee that we have enough data to proceed with data augmentation, we only keep datasets with artificially generated minority classes that have more than two elements. For reasons of clarity, we denote our datasets from the UCR Time Series D_i with $i \in [1, ..., n]$. Furthermore, in the case of a modified dataset, we denote $D_{i_-j_-k}$ as the D_i data set whose class j is reduced by k %. A matching table of the new names and the original names can be found in Appendix .1.2.

472

473

To gain deeper insights into the effectiveness of each data augmentation technique, we extract relevant characteristics from the dataset and analyze their influence on the performance of the classifier. This analysis helps us to determine the relationship between data augmentation techniques and the dataset. In other words, which data augmentation techniques are more suitable for a given dataset based on its inherent characteristics.

To obtain a solid base of features that characterize 509 our datasets, we first refer to *hctsa* toolbox [2]. The 510

hctsa framework incorporates a diverse range of algorithms to extract 7658 features from time series data. These encompass fundamental statistics, linear correlations, stationarity measures, entropy computations, and techniques from nonlinear time series analysis. It also involves evaluations of linear and nonlinear model parameters, fits, and predictive capabilities. In particular, hctsa integrates methods from various disciplines, including physics, making it a comprehensive tool for time series analysis. However, the extensive number of features contributes to the computational complexity, and the similarity among several of these features diminishes the significance of certain ones.

Catch22 [3] introduces a method to infer small sets of time series features that ensure strong classification performance and minimize redundancy between features.

To achieve this, it first removes features that are sensitive to mean and variance, as well as features that return special values. Then, it scores the performance of individual remaining features across classification tasks using a decision tree model and a given number of crossvalidation for each classification task. Each feature is ranked based on their performance score. The objective is to cluster the subset of the β -highest performing using the Pearson correlation distance d = 1 - r, with r the Pearson correlation coefficient between feature scores. Finally, they selected a single feature to represent each cluster based on their score and their interpretability according to them. In the end, catch22 extract 22 features that approximate the classification performances from the initial features to 90% and compute much faster. A more concrete description of each feature can be found at [11].

Secondly, we refer to [1] who extracted 6 characteristics at the data set level. Its objective was to empirically analyze which data augmentation techniques are most suitable to which deep learning model when it comes

498

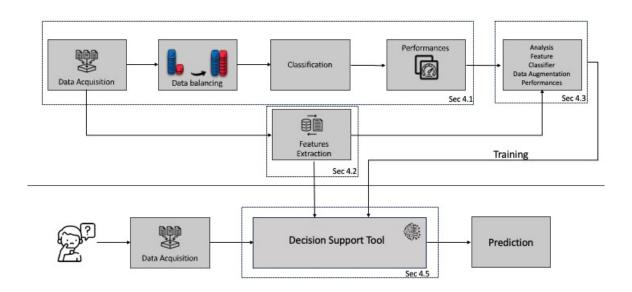

Figure 4: Caption

to classification. We further explore this direction by incorporating additional characteristics at the dataset level. One of these additional features we take into account is class separability. We believe that a clear distinction between classes allows greater flexibility in applying data transformations, as well as improved differentiation in learning patterns among classes using learning techniques. Conversely, when class boundaries are unclear, it results in less flexibility for generating accurate new data through transformations. To estimate the class separability we refer to [12], who initially 541 introduced the Gaussian Bhattacharyya Coefficient (GBC) with the idea of measuring the overlap between target classes in the feature space of machine learning model for transferability purposes. Here we use this metric to measure ovelap directly on the input dataset.

534

535

Gaussian Bhattacharyya Coefficient. The Gaussian Bhattacharyya coefficient measures the overlap between two multivariate Gaussian distributions.

Let μ_{c_i} and μ_{c_i} (resp. Σ_{c_i} and Σ_{c_i}) be the mean vector (resp. covariance matrix) of class c_i and c_j . We denote $\Sigma = \frac{\Sigma_{c_i} + \Sigma_{c_i}}{2}$ and the Gaussian Bhattacharyya Coefficient between c_i and c_j as:

$$GBC\left(c_{i},c_{j}\right) = \sqrt{\frac{\sqrt{\left|\Sigma_{c_{i}}\right|\left|\Sigma_{c_{j}}\right|}}{\left|\Sigma\right|}}\exp\left(-\frac{1}{8}t\left(\mu_{c_{i}}-\mu_{c_{j}}\right)\Sigma^{-1}\left(\mu_{c_{i}}-\mu_{c_{j}}\right)\right)$$

Finally, we have:

$$GBC = \sum_{i < j} GBC(c_i, c_j)$$

A GBC value equal to zero corresponds to a dataset with completely distinct classes.

We gather all the data-level and dataset-level features used in Table 2.

4.3. Decision Support Model

Exploring the intricate relationships between dataset features and classification performances when harmonizing with data augmentation can be challenging. Furthermore, it can be difficult for practitioners to discern which technique is most appropriate for each feature and to formulate a comprehensive classification of the techniques to be implemented. Indeed, complex relationships can exist across multiple features.

To address this issue, we examine data pairs (X_i, Y_i) , where X_i symbolizes the input feature vector corresponding to the i^{th} dataset D_i over the all n datasets, consisting of 29 unique characteristics denoted as $(x_{i1}, x_{i2}, \ldots, x_{i35})$. The 29 features, x_{ij} , encapsulate specific information as per Table 2.

 Y_i denotes the output performance vector corresponding to the i^{th} sample, composed of 42 features for each of the scenario classifier / data augmentation.

Table 2: Time series features extracted from [1] and catch22

7	
Feature	Description
Dataset Level	
Dataset size (DS)	Number of time series in the input dataset
Length (L)	Length of time series in the input dataset
Average Patterns per Class (APC)	Average count of data occurrences in each class
Dataset Variance (DV)	Average variance of each component of time series in the dataset
Intra-class Variance (IV)	Average variance per class (element-wise)
Class Imbalance (ID)	Measures the distribution of classes. A larger value indi- cates a non-equitable distribution, 0 indicates an equitable distribution
Gaussian Bhattacharyya Coefficient (GBC)	Measure of the class overlapping
Data Level	measure of the class overlapping
Distribution Distribution	
DN_HistogramMode_5 (DN5)	Most dominant z-score range based on the highest count of a 5-bin histogram
${\tt DN_HistogramMode_10}~(DN10)$	Most dominant z-score range based on the highest count of a 10-bin histogram
Temporal Statistics	
SB_BinaryState_Mean_Longest(SB)	Longest period of consecutive values above the mean
DN_OutlierInclude_p_001_mdrmd (DNOp)	Time intervals between successive extreme events above the mean
DN_OutlierInclude_n_001_mdrmd (DNOn)	Time intervals between successive extreme events below the mean
Linear autocorrelation	
CO_flecac (COfl)	First 1/e crossing of autocorrelation function
CO_FirstMin_ac (COfi)	First minimum of autocorrelation function
SP_Summaries_welch_rect_area_5_1 (SPa)	Total power in lowest fifth of frequencies in the Fourier power spectrum
SP_Summaries_welch_rect_centroid(SPc)	Centroid of the Fourier power spectrum

Transition from time-series data to tabular data for 604 the purpose of characterizing datasets. This shift in per- 605 spective leads us into the realm of tabular data regression models, with the goal of predicting the estimated performance of our time-series classification models. In the study conducted by Borisov et al. in 2021 [13], a comprehensive benchmarking was carried out to assess the efficacy of various models for tabular data, ranging from gradient boosting models to deep neural networks. The findings of this investigation indicate that, despite significant advances in deep learning within the field of machine learning, gradient boosting models such as CatBoost [14], XGBoost [15] or LightGBM [16] continue to exhibit superior performance compared to all other state-of-the-art models. Gradient Boosting constructs a model in a stage-wise fashion and is renowned for optimizing an arbitrary differentiable loss function, allowing for enhanced predictive accuracy and model generalization across diverse dataset features.

We train a Gradient Boosting model, to predict Y_i 612 based on X_i , thereby capturing the intricate relationships 613 between the characteristics of the data set and the performance after balancing. This model allows us to delve 615 into the complex interplay between different features 616 and classification performances, providing a deeper understanding of the impact and efficacy of various data 618 augmentation techniques.

To evaluate the performance of our model, we employ two metrics to compare the predicted values \hat{Y} against the actual values Y. Since our initial problem is a regression task, we first use the Root Mean Square Error (RMSE) defined as:

$$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^{n} (\hat{y}_i - y_i)^2}$$

Furthermore, to determine the effectiveness of recommending the optimal technique, we rank each value in Y from the best to the worst, generating a ranked list, denoted Y_r . For example, if Y = [0.12, 0.15, 0.99, 0.56] , then the corresponding ranking list would be $Y_r = \frac{629}{629}$ [4, 3, 1, 2].

We denote Y_r as the actual ranked list and \hat{Y}_r as the predicted ranked list. We employ Kendall's Tau, τ , to assess the agreement between the rankings of Y_r and \hat{Y}_r . 633 It is computed as follows:

$$\tau(Y_r, \hat{Y}_r) = \frac{C - D}{\sqrt{(C + T_{Y_r})(C + T_{\hat{Y}_r})}}$$

Here, C represents the number of concordant pairs between Y_r and \hat{Y}_r , D represents the number of discordant pairs between Y_r and \hat{Y}_r , T_{Y_r} is the number of pairs

tied in Y_r and $T_{\hat{Y}_r}$ is the number of pairs tied in \hat{Y}_r . The value of τ ranges from -1 to 1; a value of 1 implies perfect concordance, -1 implies perfect discordance, and 0 denotes no correlation between the rankings.

5. In practice

In this section we explore the experimental results of our study. Specifically, in 5.1 we present in details the experimental parameters that we used, in 5.2 we discuss the correlation analysis between the characteristics and the improvement after and before balancing:

$$\Delta_{F1} = F1_{after} - F1_{before}$$

It turns out that there is a mixed type of relationship based on the chosen classifier and data augmentation techniques. These multivariable complex relationship between features, classifier, data augmentation techniques used, and performances lead to development of a machine learning model that can predict which scenario is the best for which data. We tackle this in 5.2.2. After validation of our model and we used eXplainable Artificial Intelligence (XAI) techniques to determine if the model deeply understand the relations extracted from the correlation analysis and if other relations rise.

5.1. Experimental Settings

We performed the preliminary experiments presented in 4 on the **XXX** datasets from the UCR time series repository and the modified siblings presented in 4.1.

We extracted the caractecrizing features from 2 for each datasets.

5.2. Exp results

5.2.1. Correlation analysis

Correlations analysis plots is shown in 5 for classifiers, all the other plots can be found in Appendix. Each row corresponds to the correlation between Δ_{F1} and the extracted dataset features for a given classifier (e.g. DTW-Neighbors for the first row).

Correlations are computed using the Spearman's rank correlation coefficient. We employ Spearman's rank correlation coefficient for the reasons detailed in [1] (can handle skewed variable distribution and robust to outliers) as well as its capacity to catch non-linear relationship between variables. To do so, it consists of estimating the correlation coefficient between the rank of the variables observations. The relationships between

635

636

dataset features and Δ_{F1} seem to be significantly impacted by the combination of data augmentation techniques and classifiers used. Unique correlations appear when certain classifiers are paired with specific data augmentation techniques, each affecting various features distinctively.

691

692

Firstly, with the MLP classifier, the correlations across all data augmentation techniques appear fairly consistent. This could be attributed to the neural network architecture's ability to discern the intrinsic information of the input data, allowing it to learn essential 702 information regardless of the applied transformations. 703 However, there are noteworthy correlations with cer- 704 tain features. Features such as DNO, ID, and COh tend to be positively correlated with all techniques, while L and PD generally show a negative correlation. With respect to scenarios involving other classifiers, there are pervasive correlations, but there are also intrinsic correlations emerging with specific augmentation techniques. For instance, Random oversampling (ROS) has a positive relationship with DNOp, except when it is used in conjunction with the MLP classifier. This effect is quite subtle. In the case of Jittering, it shows 714 significant behaviors with certain features; MD and SB 715 tend to be positively and negatively correlated with Δ_{F1} , 716 respectively, when used with RandomForest and TS- 717 RandomForest. Additionally, with the KERNEL clas-718 sifier, unique correlations appear: DNOn is negatively 719 correlated, while DN10 and DN5 show positive correlations. This pattern is intriguing because other techniques do not exhibit similar behavior. Time warping augmentation exhibits a distinctive behavior. For all classifiers, except MLP, it presents a higher positive correlation compared to other techniques. Specifically, it is 725 the only technique that reveals significant correlations 726 with certain features (DN5 and DN10) when applied 727 with the DTW-NN classifier. SMOTE and ADASYN exhibit similar trends, particularly showing negative correlations with DN5 and DN10 when paired with the kernel classifier. As for the DTW-SMOTE technique, its correlations are somewhat comparable to SMOTE 732 and ADASYN, but with lower values, except when used 733 with the KERNEL classifier, where elevated values are 734 observed.

This correlation analysis sheds light on the relationships between Δ_{F1} , dataset features, models and the applied oversampling techniques. It is crucial to recognize that these observed correlations may not encapsulate the full complexity of the interactions involved. The analysis might not be exhaustive enough to recommend a definitive data augmentation technique, as these methods come with their subtleties, influencing the dataset 742

and classifiers beyond what the correlation metrics can convey.

5.2.2. Model building & training/testing

We created a relevant dataset using the results of the experiment described in 3. To find the best hyperparameters for our model, we conducted a grid search (learning rate: 0.04321, max depth: 7, n estimators: 477, gamma: 0, subsample: 0.5713, colsample bytree: 0.6081, reg alpha: 0.1, min child weight: 5, scale pos weight: 1). The dataset is divided into training and testing sets with an 80/20 split. To gain a more comprehensive understanding of the model's effectiveness, we applied a 10-fold cross-validation.

The results obtained from the test set are summarized in Table 4. Predictions were categorically grouped per model to facilitate a systematic ranking among the various data augmentation techniques. The global mean of Kendall's tau was used to compare the predicted optimal data augmentation techniques with their actual optimal technique. Additionally, both the Mean Squared Error (MSE) and variance were computed for each grouped prediction. The estimated performance prediction, when employing data augmentation, was found to be notably commendable. Furthermore, considering that all data augmentation techniques can result in closely related performance scores in certain scenarios, Kendall's tau serves to indicate the capability of the model to accurately rank the different data augmentation techniques. Evidently, the model demonstrates considerable ranking efficacy in all scenarios. Specifically, the model has a remarkable ability to decide which data augmentation technique should be used for oversampling in conjunction with various models such as Random Forest, Kernel, MLP, and DTW-NEIGHBORS. This is evidenced by a strong Kendall's tau value exceeding 0.7, illustrating the model's robust and relevant augmentation ranking capabilities. For TS-Random Forest and Shapelet models, the model faces slight challenges, reflected by a modest Kendall's tau value above 0.4. Despite this, the model still maintains an acceptable level of effectiveness in ranking the augmentation techniques. More detailed results can be found in the appendix.

5.3. Feature Importance

One of the key benefits of employing gradient-boosting methods lies in their interpretability. Determining the importance of features in these models is a straightforward process. In their work, [17] introduced SHAP, a unified approach that improves our understanding of model predictions. SHAP enables us to precisely

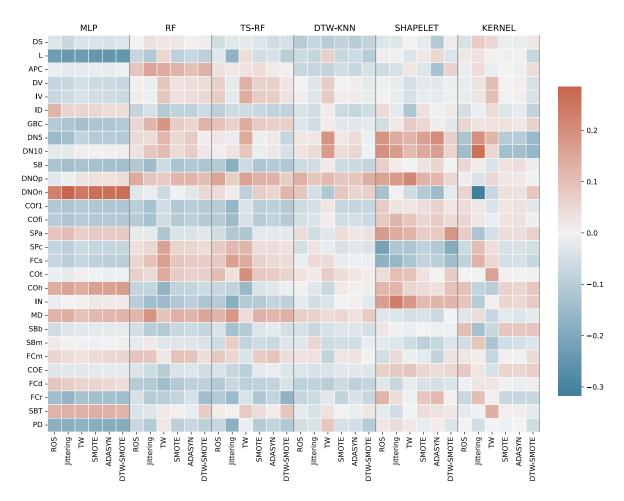

Figure 5: Correlation between features and Δ_{F1}

Model	Kendall's Tau	MSE
Random Forest	0.73 ± 0.08	$1e-2 \pm 3e-4$
TS Random Forest	0.46 ± 0.06	$1e-2 \pm 5e-4$
Kernel	0.79 ± 0.04	$3e-3 \pm 5e-5$
Shapelet	0.43 ± 0.11	$3e-2 \pm 2e-5$
MLP	0.91 ± 0.01	$1e-2 \pm 4e-6$
DTW-NEIGBORS	0.77 ± 0.07	$1e-2 \pm 1e-3$

Table 3: Comparative Analysis of Model performance on Test set using Kendall's Tau and MSE $\,$

assess which features carry the most significant weight 767 in a model's predictions, offering concrete insights into 768 their impact. Therefore, we use eXplainable Artificial 769 Intelligence (XAI) techniques to gain insight into the inherent connections between features and the classification performance learned by our model. This approach 772 enables us to determine whether BALANCER captures 773 the same relationships as identified in our earlier study. Furthermore, it empowers us to investigate whether the 775 model uncovers previously undiscovered, deeper connections.

In 6, a summary plot illustrates the 10 most impor-

tant characteristics of time series datasets given to each of the data augmentation techniques. Features are methodically ranked in ascending order, with the most critical feature prominently displayed at the top. The x-axis delineates the impact, either positive or negative, of the corresponding characteristic values. A shade of red indicates a high value of the feature, while blue signifies a low value. This visual representation assists in comprehending the significance and influence of each feature, facilitating an informed evaluation of the data augmentation techniques in the context of the respective timeseries datasets.

SHAP values have revealed notable trends in our model, showing the various effects of individual features in forecasting results when applied for balancing purposes through multiple data augmentation techniques. Notable characteristics like ID, Battacharyya (GBC), dataset variance (DV), dataset size (DS), and DNOp are consistently found to be highly significant. A careful examination reveals subtle connections between data augmentation strategies and certain characteristics. The ID feature dominates consistently, always securing the top ranking position in all techniques, affirming its universal influence. On the contrary, features

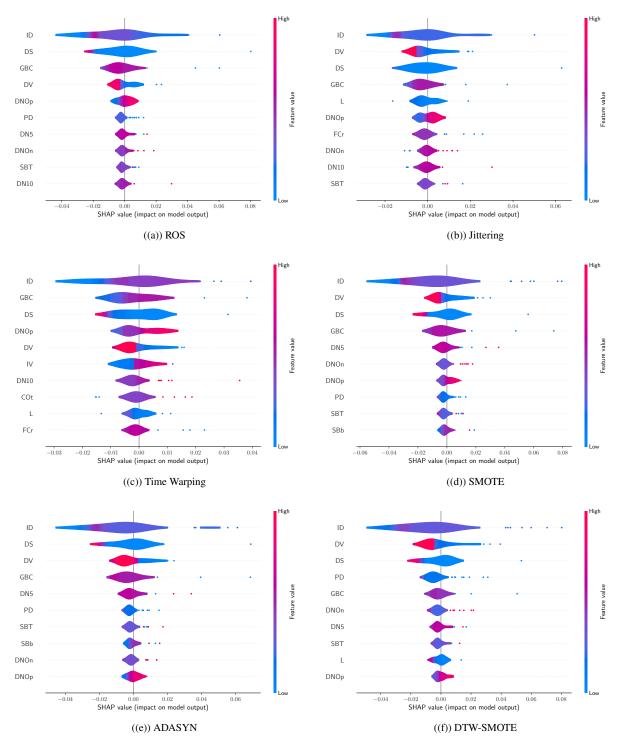

Figure 6: Mean TOP 10 shapeley values from (a) Random Oversampling, (b) Jittering, (c) Time Warping, (d) SMOTE, (e) ADASYN and (f) DTW-SMOTE

such as GBC, DN_HistogramMode_10/5(DN10, DN5), DV, PD, and length (L) demonstrate variability in their significance, revealing that their impact is contextually dependent on the applied data augmentation technique.

This exploration delineates four behaviors among the top ten critical features:

Ascendant Features: These enhance model performance when values are higher and, inversely, diminish performance when values are lower.

Descendant Features: These improve performance when values are lower, while higher values tend to reduce performance.

Uniform Features: These features maintain a consistent type of value, predominantly high or low.

Complex Features: Exhibiting intricate relationships, these features do not conform to straightforward influences on performance.

Examining the ROS technique reveal DNOp as an ascendant feature, where larger temporal intervals between extreme events relative to the mean enhance model performance. On the contrary, features such as DS and DV emerge as descendant features, suggesting that larger and more volatile datasets under the ROS technique. Horover, several features, including GBC, DN5, by DNOn, SB_TransitionMatrix_3ac_sumdiagcov (SBT), and DN10, manifest themselves as complex features, highlighting significant, though mixed, influences on the model.

Using the Jittering technique, features such as DNOp soft continue to assert themselves as ascendant features, increasing Δ_{F1} when the time gap between extreme occurrences is considerable. Unique to Jittering, DS and L appear as uniform features, where smaller datasets and shorter time series optimally influence model performance.

Time Warping reflects DNOp as a predominant ascendant feature. Meanwhile, DV and DS emerge as descendant features, displaying an adverse effect on performance with larger and more variable datasets.

A pattern of feature importance is evident when considering SMOTE, ADASYN, and DTW-SMOTE, although there are slight variations. DNOp is consistently the most influential feature, leading to improved performance with these techniques. On the contrary, DS and bV typically act as descendant features, where larger or more variable datasets seem to hinder Δ_{F1}

The results demonstrate the intricate nature of determining clear connections between the characteristics of a dataset and the enhancement of performance. They accentuate the multifaceted interactions among features, affirming that while individual features maintain intrin-

Top Important Feature	Correlations	SHAP
ROS	DNop	$5e-3 \pm 2e-6$
Jittering	0.75 ± 0.06	$6e-3 \pm 5e-6$
Time Warping	0.76 ± 0.06	$5e-3 \pm 2e-6$
SMOTE	0.77 ± 0.03	$7e-3 \pm 1e-5$
ADASYN	0.73 ± 0.06	$6e-3 \pm 4e-6$
DTW-SMOTE	0.76 ± 0.03	$6e-3 \pm 5e-6$

Table 4: Comparative Analysis of Model performance on Test set using Kendall's Tau and MSE

sic significance, their collective interplay profoundly influences model behavior. Using a Gradient Boosting model aims to capture theses complex relationship, it can be complicated to represent them in a single dimension.

5.4. Comparison between correlations and feature importance

The empirical analysis allows us to identify meaningful connections between features and the improvements made possible by different data augmentation techniques based on correlation. Additionally, our model shows varying results when trying to determine which data augmentation technique is most suitable. Examining the knowledge from our model and comparing it to the dependencies found in the empirical study not only verifies some previously discovered relationships but also gives a deeper understanding of the essential dataset features when practitioners want to use data augmentation on an imbalanced time-series dataset. When comparing the correlation from Figure .5 with feature importance from Figure 6, intesting insight emerge. First, many highly correlated features for a given augmentation technique are present as the most important feature related to the augmentation technique for BAL-ANCER (e.g. DNOp when used with ROS; L, DNOn and SBT when used with Jittering; SBb when used with SMOTE & ADASYN). Moreover, an intriguing observation emerges from comparing features with complex behaviors with SHAP value importance against their correlation coefficients. They seem to have minimal correlations. This notable observation underscores the limitation of relying solely on simple correlation analyses, as they might not fully unveil the multifaceted relationships that certain features share with others.

Such a phenomenon emphasizes the need to go beyond basic correlation analyses. Using machine learning models ability to capture these nuanced relationships accentuates the need to employ more sophisticated analytical approaches to unravel the complexity of interactions amongst features using XAI techniques such as SHAP. In the case of this study to enravel the intrinsic link existing between datasets features, oversampling statesgies through several state-of-the-art data augmentation techniques and the link improvement of performance.

5.5. Mise a disposition de nos modèles pour un praticioneur

The prediction model discussed in this paper offers an accurate way to estimate the performance improvements achieved when balancing a time series dataset for classification tasks. It has been extensively trained on a diverse set of 800 example datasets that encompass various scenarios, including different classifiers and data augmentation techniques. Additionally, it has the ability to reliably rank these techniques based on the F1 score achieved after balancing.

A primary advantage of this model lies in its ability to assist practitioners in selecting the most suitable data augmentation technique, thereby saving them valuable time. The model can quickly generate predictions within a matter of seconds, helping practitioners make informed decisions about the optimal data augmentation approach to use with the aim of balancing their dataset.

In order to quantify the imbalance of a dataset, we re- 1010 fer to the distribution of the different classes inherent to 1011 it. Let's consider a dataset with K classes. We denote 1012 $(c_1,...,c_K)$ the K classes and $\zeta = (\zeta_1,...,\zeta_K)$ their distri- 1013 butions. Thus each ζ_i estimates the probability of each 1014 class c_i by simply determining the frequency of class c_i in the data set. Formally

$$\zeta_i = \frac{1}{n} \sum_{k=1}^n \mathbb{1}(Y_k = c_k)$$

where n is the number of data in the dataset and Y_k the label of the k th data. Class c_i is said to be a minority class when $\zeta_i < \frac{1}{K}$. Reciprocally c_i is said to be a majority class when $\zeta_i > \frac{1}{K}$. In the case of a fully balanced dataset, we note $\zeta_{eq} = e = (\frac{1}{K}, ..., \frac{1}{K})$

This description of the class distribution seems to be a good choice to compare datasets between them. However, their analysis can be quite tedious in problems with a large number of number of classes, or when studying datasets with a different number of classes.

In the literature, many measures exist to quantify the imbalance of a dataset. These measures are used to 1015 compare datasets and describe how unbalanced they are. 1016 One of the most use measure is Imbalance Ratio (IR) [] 1017 corresponding to the ratio between the number of el- 1018 ements of the most majority class and the number of 1019 elements of the most minority class

$$IR(\zeta) = \frac{max_i\zeta_i}{min_i\zeta_i}$$

This measure is relevant to study data sets with two 1024 classes since it is injective, i.e. each distribution of two 1025 classes has a different measure. Thus each possible sce- 1026 nario can be found from an IR measure. However, the 1027

measure becomes obsolete for K > 2 (loss of injectivity and difficulty to estimate the order of magnitude of the measures).

Imbalance Degree or (ID) [] is based on the idea of extending the injectivity of IR for any K and having a defined interval of values for the measure. By subdividing the space of possible distributions into m subspaces corresponding to distributions with m minority classes, this measure gives values in the interval (m-1;m]. Moreover, this measure allows to choose between different metrics or divergences d_{Λ} to compare distributions.

$$ID(\zeta) = \frac{d_{\Delta}(\zeta, e)}{d_{\Delta}(\iota_m, e)} + (m - 1)$$

where m is the number of minority classes, d_{Δ} is the chosen distance/divergence and i_m is the distribution showing exactly m minority classes with the largest distance from e. In practice this measure is complicated to use because of the interval in which the measure lies. It is only relevant to compare two distributions if they have the same number of minority classes.

Figure .7: Imbalanced dataset distribution

The imbalance data sorely impacts classical classification methodes. This is due to the fact that the majority of classification algorithms aim at maximizing accuracy and minimizing overall error.

Considering an example of classification with a very imbalanced dataset with three classes such that $\zeta = (0.98, 0.01, 0.01)$. Let us consider a bad classifier which classifies all data as belonging to class 0. We then obtain 98% accuracy. This measure indicates that the classifier is good even though no class 2 and 3 data have been well classified.

It is therefore necessary to introduce measures that provide more accurate information on each information

1021

1022

on each class.

Precision is the ratio of the number of data correctly assigned to a class with to total number of data assigned to class A. It measures the correctness of a classifier.

Low precision indicates a high number of false positives.

Recall is the ratio of the number of data correctly assigned to class A to the total number of data actually belonging to class A. It measures the completeness of a classifier. A low sensitivity indicates a high number of false negatives.

F1-score =
$$2 * \frac{Precision * Recall}{Precision + Recall}$$

F1-score computes harmonic mean of precision and recall by class. The scores of each class are averaged to obtain a single measure call macro F1-score.

G-mean =
$$\sqrt{\text{Precision} * \text{Recall}}$$

The geometric mean (G-mean) measures the balance 1085 between precision and recall. For binary classification 1086 G-mean is the squared root of the product of the precision and recall. For multi-class problems it is a higher 1088 root of the product of recall for each class. The scores 1089 for each class are averaged for the scores of each class 1090 to obtain a single measure.

$$MCC = \frac{TP * TN - FP * FN}{\sqrt{(TP + FP)(TP + FN)(TN + FP)(TP + FN)}} \frac{1093}{1095}$$

where

- TP: True Positives
- FN: False Negatives
- FP: False Positives
- TN: True Negatives

Matthew's Correlation Coefficient (MCC) is a corre- 1105 lation coefficient between actual and predicted between 1106 real and predicted classes. The value varies from -1 to 1107 +1 with a value of +1 representing a perfect prediction, 1108 0 being no better than a random prediction and -1 the 1109 worst possible prediction.

Models

Multilayer Perceptrons (MLPs) are basic neural network architectures consisting of multiple layers of interconnected nodes. For benchmarking, we used an MLP with a specific architecture: time series input, followed by a dense layer with 64 neurons, rectified linear unit (ReLU) activation, dropout regularization (rate = 0.1), and classification output. We train the MLP for 100 epochs with a batch size of 32.

The **Random Forest** (RF) classifier is an ensemble model that combines multiple decision trees. For our benchmarking tests, we employ a Random Forest with 130 decision trees and a maximum depth of 50. The remaining hyperparameters are set to their default values.

The **TimeSeries Random Forest** (TS-RF) is a variation of the Random Forest algorithm specifically designed for time series data. It extracts time series features, such as mean and standard deviation, before constructing the ensemble of decision trees. We keep the same hyperparameters as Random Forest.

The **Dynamic Time Warping** *K***-nearest neighbors** (DTW-KNN) classifier assigns a time series to the majority class among its nearest neighbors in the feature space, using the Dynamic Time Warping (DTW) distance metric. DTW measures the similarity between two time series, considering possible distortions in their temporal alignment. DTW is more appropriate than the Euclidian distance in the context of time series.

The **ROCKET Kernel** classifier is a kernel-based algorithm that uses random convolutional kernels to find important patterns in time series data. It analyzes segments of the data and converts them into a high-dimensional representation. For the benchmarking, we utilize 10,000 random convolutional kernels.

The **Shapelet** classifier extracts discriminative subsequences, called shapelets, from time series data. The classifier selects the most relevant shapelets and uses them for classification.

Data augmentation techniques

Appendix .1. Data generation methods

Many data generation techniques exist for the time series. These techniques can be divided into two main types of approaches: (i) basic techniques grouping together simple transformations in the temporal and frequency domain and (ii) advanced techniques grouping together learning methods and generative models.

Since data augmentation relies on generating new synthetic data from initial data, we make the assumption that all new generated data belong to the same class

Table .7: Test set Mean Squared Error per scenario model / data augmentation technique

as the initial data. This hypothesis will be discussed 1129 later. Moreover, we consider only univariate time series 1130 to keep things simple first. In the rest of the paper, a 1131 (univariate) time series of length t is defined as a finite 1132 sequence $X := (x_1, \ldots, x_t) \in \mathbb{R}^t$.

Appendix .1.1. Basic techniques

We take six popular basic techniques to generate synthetic data.

Random Oversampling (ROS) consists of randomly 1139 duplicating data from the minority class to the minority 1140 class to rebalance the dataset. It is a simple and straight- 1141 forward method to address class imbalance but naive as 1142 it does not add any variations to the synthetic samples. 1143

Jittering is one of the most basic transformations. 1144 It involves adding noise to the time series. Let X := 1145 $(x_1, ..., x_t)$ be a real time series. Then, jittering is able 1146 to create a new sample $X' = (x_1 + \varepsilon_1, ..., x_t + \varepsilon_t)$ 1147

where $\varepsilon_i \sim \mathcal{N}(0, \sigma^2)$ are independent and identically distributed (iid). The standard deviation σ is a hyperparameter that determines the amplitude of the added noise. In practice, σ^2 is set to 0.03. []

Time warping acts the same way as Jittering and consists of slightly distorting the initial data. However, the distortion takes place in the temporal environment. Let $X := (x_1, ..., x_t)$ be a real time series. Then we have $X' = (x_{\tau(1)}, ..., x_{\tau(t)})$ where $\tau : t \to \tau(t)$ is the warping function which distorts the time steps using a *smooth* function. This function is defined by a Hermite cubic spline, which allows to generate a polynomial interpolating a function between points $u = (u_1, ..., u_I)$ such that each u_i are independent and identically distributed with $u_i \sim \mathcal{N}(\mu, \sigma^2)$. Thus, the time steps of the series present a smooth transition between stretches and contractions. This technique requires solving a complex optimization problem and can be be computationally time consuming.

Synthetic Minority Oversampling TEchnique 1181 (SMOTE) is one of the most popular approaches. It cre- 1182 ates new minority individuals that look like the others, 1183 without being strictly identical, and densifies the pop- 1184 ulation of minority individuals more homogeneously[]. 1185 SMOTE generates new instances by interpolating ex- 1186 isting neighbor samples selected through the K-Nearest Neighbors algorithm based on Euclidian distance. To generate new samples, a time series X_0 is uniformly chosen from the minority classes. Let X_1, \ldots, X_K be its K nearest neighbors of the same class. SMOTE generates K new samples as follows:

$$X'_1 := X_0 + \lambda_1(X_1 - X_0)$$

$$\vdots$$

$$X'_K := X_0 + \lambda_K(X_K - X_0)$$

where $\lambda_i \sim \mathcal{U}([0,1])$ iid.

Adaptive synthetic (ADASYN) is a variant of SMOTE where new data are generated predominantly at the class boundaries, where classification is most challenging. Unlike SMOTE, which uniformly selects a data point X_0 , ADASYN tends to choose data points in dense neighborhoods with samples of the majority class.

DTW-SMOTE is also a variant of SMOTE that uses the DTW distance instead. The use of Euclidean distance in SMOTE may not be suitable for comparing time series. For example, a cosine wave and a sine wave are likely considered different based on the Euclidean norm, even though they are intuitively similar because they only differ with a temporal shift. Thus, it is relevant to use DTW instead which measures the similarity between two time series, taking into account temporal shifts.

Appendix .1.2. Advanced techniques

TimeGAN [J Yoon, D Jarrett, M Schaar. Timeseries Generative Adversarial Networks. NeurIPS 2019; 2019.] is a Data Augmentation method based on Generative Adversarial Networks (GANs). GANs involve training two neural networks to compete against each other, one generating synthetic data and the other discriminating between synthetic and real data. TimeGAN is specifically designed for time series data. It incorporates additional embedding components to capture the temporal characteristics of the time series.

Schrodinger Bridge is a recent generative model for time series based that belongs to the category of scorebased models [M Hamdouche, P Henry-Labordere, H Pham. Generative modeling for time series via

Schrödinger bridge.; 2023]. It involves the entropic interpolation through optimal transport between a reference probability measure on path space and a target measure that aligns with the joint data distribution of the time series. [A VOIR SI ON GARDE CA, PARCE QUE C'EST PAS OUF]
